ABSTRACT

Foot & Ankle arthroscopy is an increasingly rapid field in the treatment of multiple hip conditions, owing to its important diagnostic and therapeutic benefit. As these patients lack a consistent pain relief plan, effective post-operative pain control appears to be a concern. Several methods were used to identify a method that decreases post-operative pain, narcotic intake and hospital and treatment system costs. This article aims to study and report the relevant findings of the previous paper “Post-operative pain management strategies in hip arthroscopy.”

Latest research encourages the use of a multimodal approach to the treatment of postoperative pain in hip arthroscopic patients. In tandem with peripheral nerve blocks or intraoperative anesthetic injection a pre- and after-operative analgesic regimen is used, patients experience lower discomfort and post-operative narcotic use. Different methods are similar in post-operative pain and opioid use. However, of those undergoing Intraarticular (IA) or Local Anesthetic Infiltration (LAI), postoperative risks relative to peripheral nervous blocks are smaller.

Latest trials have demonstrated that the best and most reliable, multi-modal treatment for the reduction of postoperative pain in these patients may be intraoperative techniques such as IA injection or LAI in combination with a pre and postoperative analgesic. Furthermore, failure to use the peripheral nerve block can result in lower anesthesia procedural fees and operating room turnover, thereby lowering patients’ costs and increasing facility effectiveness.

INTRODUCTION

The Foot & Ankle arthroscopy is gaining in popularity among the orthopedic surgeons because of its important diagnostic and therapeutic importance in the treatment of common hip disorders such as Femoroacetabular Impingement (FAI). While the prevalence of hip arthroscopy for the treatment of hip disease has improved lately, post-operative pain relief appears to be a formidable task for orthopedic surgeons. There is a lack of consistent guidelines for hip arthroscopy postoperative pain relief, possibly because of the lack of high-quality comparative trials investigating the feasibility of multiple therapies.

The aim of PPMMS in hip arthroscopy [1] was to provide a detailed, up-to-date analysis. Present postoperative pain control literature Hip arthroscopy procedures in patients. It also provides a source for orthopedic surgeons to decide which procedure, or variation thereof, in hip arthroscopy is appropriate for their practice and patients. This statement is intended in advance to review the most relevant conclusions of Hip Arthroscopy Postoperative Pain Relief Strategies [1] and to focus on the potential effects of this paper.
**IMPERATIVE CONCLUSIONS**

Several new experiments have shown the efficacy of oral drugs for pain relief in the patients who undergo severe orthopedic surgery, such as acetaminophen, gabapentin, and cyclobenzaprine [2–4]. However, these medications have not been tested thoroughly in hip arthroscopy patients. On the opposite, Celecoxib has been extensively tested in hip arthroscopies and has demonstrated its high oral bioavailability, fast absorption and selective cyclooxygenase (COX)-2 inhibition to make it an effective oral anti-inflammatory (NSAID) [5]. Preoperative celecoxib resulted in slightly lower pain scale (VAS) of 1, 12 and 24 hours postoperatively compared with placebo [5,6] in two randomized controlled trials. In comparison, patients getting celecoxib spent less time in the PACU than in placebo [5,6].

There has been growing interest in treating the postoperative pain of hip arthroscopic patients with the use of peripheral nerve blocks, such as Lumbar Plexus Block (LPB), Femoral Nerve Block (FNB) and Fascia Iliaca Block (FIB). The VAS pain values in PACU is statistically, though not clinically substantially lower than that of general anesthesia alone, or placebo [7,8] for patients suffering from LPB. However, patients with LPB required fewer postoperative narcotic, anti-emetic and ketorolactic drugs than the control group [7]. In patients receiving FNB, intraoperative and postoperative opioids are usually less necessary than in patients receiving general anesthesia alone or placebo [9,10]. In patients receiving FNB pain values were lower than in general anesthesia alone, but in the PACU period was higher in patients receiving FNB [10]. Importantly, patient satisfaction was higher, and the discharge period was shorter in FNB patients compared with pain IV morphine [11] patients. In PACU, FIB patients were reasonably successful (3.85/10) [12] during hip arthroscopy.

Although peripheral nerve blocks can alleviate postoperative pain effectively, they are not complicated. Intravascular injection, iatrogenic nerve trauma, postoperative slips, inflammation and rebound pain following discharge are risk for peripheral nerve blocks [13–15]. Furthermore, peripheral nerve blocks require specialist instruments and an anesthesiologist to operate them and raise patient and hospital costs.

Local Intra-Articular (IA) anesthetic injections have proved similarly successful relative to FNB. Child, et al. [14] recorded no major difference between FNB and pain scores for 1, 3 and 6 weeks. Importantly, postoperative drops were slightly smaller in the IA injection community (5 vs 19, \( p < 0.001 \)). In the IA injection group, there was also a lower prevalence of postoperative peripheral neuritis relative to the FNB group (2 vs 26 \( p < 0.001 \)). IA injection of local anesthetics thus offers a beneficial alternative to FNB for post-operative pain relief, since the treatment is greatly minimized and the pain values are identical to FNB. In PACU, preoperative celecoxib with acetaminophene and IA injection with morphine and clonidine is greatly reduced as compared to patients who administered oral analgesics alone. However, there were comparable pain ratings between the two classes and no major gap in time for release [16]. Thus, clonidine and morphine IA injection can decrease complications associated with postoperative opioid use, such as respiratory distress and dependence, while providing sufficient analgesia to hip arthroscopy patients.

Local Anesthesia Penetration (LAI) has increasingly become an important option for orthopedic surgeons to costly operations, such as peripheral nerve blocks. In a research carried out by Philipp, et al. [17], intraoperative LAI patients called for fewer postoperative femoral nerve blocks in comparison to the non–LAI community. However, no substantial difference was found between the PACU classes in opioid intake (\( p = 0.740 \)) [17]. In contrast to FIB, patients getting LAI had less discomfort after surgery. Furthermore, the total intake of morphine in the LAI group was twice as low, resulting in less nausea and vomiting than that of the FIB group 24 hours later [18]. Of note, patients receiving LAI required considerably more rescue medicines in contrast to LAI injection (2.33 mg vs. 0.57 mg, \( p = 0.036 \)). However, VAS pain ratings did not vary statistically among the groups at 1 to 2 hours after surgery. Thus, LAI is a successful treatment with comparable pain relief effects to peripheral nerve blocks, without intravascular injection risks, iatrogenic nerve disruption, postoperative slips and higher patient and hospital costs. The surgeon performs LAI intraoperatively and does not require ultrasound advice that will decrease the turnover of the operating room time.

**IMPLICATIONS**

The reports in recent literature endorse the use of a multimodal approach to postoperative pain control in hip arthroscopy patients. When a multi-modal strategy is employed that is a pre- and postoperative analgesic regime, in tandem with peripheral nerve block or intraoperative anesthetic injection, patients have less pain and postoperative narcotic ingestion. Different methods are similar in post-operative pain and opioid use. However, post-operative symptoms are fewer compared to peripheral nerve blocks in those undergoing IA or LAI. Furthermore, peripheral nerve blocks can lead to intravascular injection, iatrogenic nervous injury and involve highly qualified anesthesiologists which result in increased costs associated with the procedure. IA injection and LAI are quick procedures by the orthopedic surgeon done intraoperatively. Using these intraoperative procedures may improve operating...
CONFLICT OF INTEREST
